Benzodiazepine withdrawal syndrome - Wikipedia, the free encyclopedia—is the cluster of symptoms which appear when a person who has taken benzodiazepines long term and has developed benzodiazepine dependence, stops taking benzodiazepine drug(s) or during dosage reductions. Benzodiazepine withdrawal is similar to alcohol withdrawal syndrome and barbiturate withdrawal syndrome. Chronic exposure to benzodiazepines causes physical adaptations in the brain that counteract the drug's effects. This is known as a tolerance and physical dependence. When the drug is removed or dosage reduced in an individual physically dependent on benzodiazepines, numerous withdrawal symptoms both physical and psychological may appear and will remain present until the body reverses the physical dependence by making adaptations to the drug-free environment and thus returning the brain to normal function. In certain selected patient groups the occurrence of withdrawal symptoms is as high as 100%, whereas in unselected patient groups more than 50% of subjects are able to discontinue benzodiazepines with mild or even no withdrawal symptoms at all. Withdrawal symptoms may persist for weeks or months after cessation of benzodiazepines. In a smaller subset of patients withdrawal symptoms may continue at a sub acute level for many months or even a year or more. Long term use of benzodiazepines may lead to withdrawal like symptoms emerging despite a constant therapeutic dose. Correctly attributing previously misdiagnosed withdrawal symptoms such as anxiety to the withdrawal effects of benzodiazepines, individualised taper strategies according to withdrawal severity, the addition of alternative strategies such as reassurance and referral to benzodiazepine withdrawal support groups increase the success rate of withdrawal. A study of the elderly who were benzodiazepine dependent found that withdrawal could be carried out with few complications and could lead to improvements in sleep and cognitive abilities. At 52 weeks after successful withdrawal a 22% improvement in cognitive status was found as well as improved social functioning.
